Two custom-made $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ p$^+$-i-n$^+$ circular mesa spectroscopic X-ray photodiodes with different diameters (200 $\mu$m and 400 $\mu$m) and a 5 $\mu$m i layer have been characterized for their response to X-ray photons within the energy range 4.95 keV to 21.17 keV. The photodiodes, operating uncooled at 30 °C, were coupled, in turn, to the same custom-made charge-sensitive preamplifier. X-ray fluorescence spectra of high-purity calibration foils excited by a Mo target X-ray tube were accumulated. The energy resolution (Full Width at Half Maximum) increased from 0.79 ± 0.02 keV at 4.95 keV to 0.83 ± 0.02 keV at 21.17 keV, and from 1.12 ± 0.02 keV at 4.95 keV to 1.15 ± 0.02 keV at 21.17 keV, when using the 200 $\mu$m and 400 $\mu$m diameter devices, respectively. Energy resolution broadening with increasing energy was attributed to increasing Fano noise (negligible incomplete charge collection noise was suggested); for the first time, the Fano factor for $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ was experimentally determined to be 0.13, suggesting a Fano limited energy resolution of 145 eV at 5.9 keV. The charge output of each system had a linear relationship with photon energy, across the investigated energy range. The count rate of both spectroscopic systems increased linearly with varying X-ray tube current up to $\sim10^7$ photons s$^{-1}$ cm$^{-2}$ incident photon fluences. The development of $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ based spectrometers is particularly important for hard X/$\gamma$-ray astronomy, due to the material’s large linear X-ray and $\gamma$-ray absorption coefficients and the ability to operate uncooled at high temperatures. I. INTRODUCTION

$\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ is a promising new material for future high temperature tolerant X-ray photodiodes. One of $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$’s favorable attributes is its relatively wide bandgap ($\sim1.9$ eV at room temperature$^1$). The number of thermally generated carriers in a wide bandgap material can be lower than in materials with narrower bandgaps at a given temperature.$^2$ Since the leakage current of photodiode detectors is fundamentally tied to the number of thermally generated carriers within the detector, wide bandgap X-ray detectors can be used at high temperatures ($\geq20$ °C) without the need for cooling systems. Much ongoing research world-wide concerns the development of wide bandgap materials for high temperature tolerant X-ray detectors, including GaAs,$^3$-$^5$ 4H-SiC,$^6$-$^8$ AlGaAs,$^9$-$^{10}$ AlInP,$^{11}$-$^{12}$ HgI$_2,$$^{13}$ TIBr$^{14}$ and CdTe and CdZnTe.$^{15}$-$^{17}$ Applications which would benefit from the development of wide bandgap X-ray detectors include those with limitations on the mass, volume, power, and/or cost of the instrumentation since elimination of the cooling systems and shielding which are often required for narrower bandgap detectors would produce real advantages. Applications in space science and astronomy are particular motivations.

$\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ is almost completely lattice matched to GaAs ($\pm0.1$% lattice mismatch).$^{18}$ Thus, high quality $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ structures can be epitaxially grown on GaAs substrates. Also, $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ benefits from a high density, which is almost twice that of Si ($4.5$ g/cm$^3$ for $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ cf. $2.33$ g/cm$^3$ for Si).$^{19}$ The high density of $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ along with the presence of In (atomic number of 49) results in better stopping power and higher quantum efficiency per unit thickness compared to Si, SiC, GaAs, and Al$_{0.52}\text{In}_{0.48}\text{P}$. This is particularly significant at higher photon energies. For instance, the linear absorption coefficient at 60 keV for $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ (15.99 cm$^{-1}$) is greater than those for Si (0.75 cm$^{-1}$), Ge (10.77 cm$^{-1}$), and GaAs (10.84 cm$^{-1}$), and almost comparable to Cd$_{1-x}\text{Zn}_x\text{Te}$ (ranging from 30.36 cm$^{-1}$ to 37.81 cm$^{-1}$, depending on the fraction $x$).$^{20}$ Hence, there is a potentially significant utility for $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$ detectors within future planetary and astrophysics missions, which require the detection of hard X-rays and $\gamma$-rays. CdZnTe detectors have been used for such applications,$^{22}$ but can suffer from performance degradation. For example, Te inclusions and polarization effects within Cd$_{1-x}\text{Zn}_x\text{Te}$ detectors$^{16}$ can cause degradation in spectral response [e.g., a relatively modest 1.6 keV Full Width at Half Maximum (FWHM) at 5.9 keV was achieved at 23 °C$^{24}$ and 1.8 keV FWHM (without tail) at 59.54 keV was achieved at 21 °C$^{17}$ despite significant worldwide efforts to develop improved CdZnTe detectors]. The best energy resolution ever recorded using a CdTe detector at room temperature was 843 eV FWHM at 59.54 keV,$^{25}$ the CdTe pixel detector was coupled to an ultra low noise CMOS charge sensitive preamplifier (1.2 e$^-$ rms equivalent noise charge with no detector connected).

Despite the desirable attributes of $\text{In}_{0.5}\text{Ga}_{0.5}\text{P}$, very little work has been carried out on the material with regard to the development of X-ray and $\gamma$-ray detectors. The first
In$_{0.5}$Ga$_{0.5}$P X-ray detectors were reported by Butera et al.,

an FWHM at 5.9 keV of 900 eV was achieved with the detectors and preamplifier operating at room temperature. In$_{0.5}$Ga$_{0.5}$P X-ray detectors have also been investigated for high temperature X-ray spectroscopy, reporting an energy resolution of 1.27 keV FWHM at 5.9 keV, at 100 °C, and 770 eV FWHM at 5.9 keV, at 20 °C. The In$_{0.5}$Ga$_{0.5}$P electron hole pair creation energy was experimentally measured between 100 °C and 20 °C by Butera et al. and was found to be 4.94 ± 0.06 eV at 20 °C. Work has been conducted on In$_{0.5}$Ga$_{0.5}$P's binary relations, GaP and InP, but both were not spectroscopic at room temperature. A GaP Schottky diode showed a response to hard X-rays (11 keV to 100 keV) at room temperature, but the individual energies were not spectrally resolved. InP detectors showed a spectroscopic response when cooled to low temperatures: a FWHM at 5.9 keV of 2.5 keV was measured at −60 °C and a FWHM at 59.5 keV of 7 keV was measured at −57 °C. It should be noted here that the InP detectors reported in Refs. 20 and 29 were not epitaxially grown but were based on bulk semi-insulating InP. The potential use of InP detectors for solar neutrino detection has also been discussed; for example, an In based detector may allow the detection of the characteristic signature of the inverse β decay of $^{115}$In.

This paper significantly extends the previous work on In$_{0.5}$Ga$_{0.5}$P for X-ray detection. Two In$_{0.5}$Ga$_{0.5}$P p$^+$-i-n$^+$ circular mesa photodiodes (one with a diameter of 200 μm; one with a diameter of 400 μm) made from the same material as reported in Refs. 26 and 27 were characterized for their response to illumination with X-rays within the energy range 4.95 keV to 21.17 keV. A Mo target X-ray tube and 9 high-purity metal fluorescence foils were used (in turn) to generate characteristic X-ray fluorescence lines which illuminated the detectors. The photodiodes were connected, in turn, to the same custom-made low-noise single channel charge-sensitive preamplifier. The X-ray fluorescence spectra accumulated with each X-ray spectrometer enabled the determination of the Fano factor of In$_{0.5}$Ga$_{0.5}$P. The response of each X-ray spectrometer was also investigated at five different fluences of X-ray photons at energies of 8.63 keV and 16.6 keV. The temperature of the detectors and preamplifier during the measurements was 30 ± 3 °C.

II. DEVICE STRUCTURE

An In$_{0.5}$Ga$_{0.5}$P p$^+$-i-n$^+$ epilayer was grown on a (100) heavily doped n$^+$ GaAs substrate by metalorganic vapour phase epitaxy (MOVPE) using trimethylgallium, trimethylindium, arsine, and phosphine as precursors, and hydrogen as a carrier gas. The spontaneous long-range ordering in the group III sublattice and related effects on the bandgap were avoided by a miscut angle of 10° toward <111> A at the epitaxial surface of the substrate. The p$^+$ layer, the unintentionally doped i layer, and the n$^+$ layer had thicknesses of 0.2 μm, 5 μm, and 0.1 μm, respectively. The doping concentration of both the p$^+$ and n$^+$ layers was ≈2 × 10$^{18}$ cm$^{-3}$. A p$^+$ GaAs layer with a thickness of 0.01 μm (1 × 10$^{19}$ cm$^{-3}$ doping concentration) was grown on top of the In$_{0.5}$Ga$_{0.5}$P p$^+$-i-n$^+$ epilayer, to help enable the formation of a good top Ohmic contact. A quasi-annular top Ohmic contact consisting of 20 nm of Ti and 200 nm of Au was deposited on the top face of each of the detectors. A planar rear Ohmic contact consisting of 20 nm of InGa and 200 nm of Au was deposited on the rear of the substrate. The fabrication of the 200 μm diameter mesa devices used in this study was achieved with chemical wet etching techniques. A 1:1:1 K$_2$Cr$_2$O$_7$:HBr:CH$_3$COOH solution followed by a 10 s finishing etch in 1:8:80 H$_2$SO$_4$:H$_2$O$_2$:H$_2$O solution was used. The top Ohmic contact covered 45% of the surface of the 200 μm diameter devices and 33% of the 400 μm diameter devices. The In$_{0.5}$Ga$_{0.5}$P photodiodes were not passivated. Both detectors were on the same die. The die was packaged in a TO-5 can and gold-ball wirebonded. The wafer’s layer structure is summarised in Table I.

## III. ELECTRICAL CHARACTERIZATION

The dark current and capacitance as functions of applied reverse bias of the In$_{0.5}$Ga$_{0.5}$P photodiodes were measured prior to illuminating the devices with X-rays. To do this, the diodes were installed inside a TAS Micro MT climatic cabinet for temperature control. The properties of the devices were measured at 33 °C, 30 °C, and 27 °C, since the X-ray measurements were to be conducted at a temperature of 30 ± 3 °C. To ensure thermal equilibrium, the diodes were left to stabilize at each temperature for 30 min before the measurements were started at each temperature. Dry N$_2$ was continuously flowed into the climatic cabinet throughout the measurements to maintain a dry environment (<5% relative humidity). Dark currents were measured using a Keysight B2981A Femto/Picoammeter as functions of applied reverse bias, $V_{AB}$, from 0 V to −30 V. The reverse bias was applied using a Keithley 2636B SourceMeter. The uncertainty associated with each current reading was 1% of the measurement plus 3 fA. The uncertainty associated with the applied reverse bias was 0.02% of the applied bias plus 50 mV.

The leakage current associated with the TO-5 package was also measured as a function of bias and temperature, and subtracted from the leakage current of the packaged photodiodes to yield the leakage current of each diode alone. The leakage currents of the packaged In$_{0.5}$Ga$_{0.5}$P p$^+$-i-n$^+$ diodes as well as the leakage currents of the diodes themselves (with the leakage current of the package subtracted) at 30 °C can be seen in Fig. 1. The equivalent noise charge of the white parallel noise, ENC$_{WP}$, at a shaping time of 6 μs, as calculated from the leakage current of the detector (see Sec. IV) can also be seen in Fig. 1.

| TABLE I. Layers structure of the In$_{0.5}$Ga$_{0.5}$P p$^+$-i-n$^+$ wafer. |
|-----------------|-----------------|-----------------|-----------------|
| Material        | Type            | Thickness (nm)  | Doping density (cm$^{-3}$) |
| GaAs            | p$^+$           | 10              | 1 × 10$^{19}$           |
| In$_{0.5}$Ga$_{0.5}$P | p$^+$           | 200             | 2 × 10$^{18}$           |
| In$_{0.5}$Ga$_{0.5}$P | i               | 5000            | Undoped                |
| In$_{0.5}$Ga$_{0.5}$P | n$^+$           | 100             | 2 × 10$^{18}$           |
| GaAs            | n$^+$ (substrate)| ...             | ...                     |

The leakage current of the packaged In$_{0.5}$Ga$_{0.5}$P 200$\mu$m diameter device at $-30$ V reverse bias, at 33°C, 30°C, and 27°C was measured to be $1.0 \pm 0.5$ pA (rms deviance). Similarly, the leakage current of the packaged In$_{0.5}$Ga$_{0.5}$P 400$\mu$m diameter device at $-30$ V reverse bias was measured to be $0.8 \pm 0.4$ pA (rms deviance), at the same temperatures. The leakage current of both packaged diodes remained $\leq 0.2$ pA ($\leq 8 \times 10^{-6}$ ENCwp at 6$\mu$s) at $-5$ V reverse bias, the reverse bias applied during X-ray measurements. The leakage current of the In$_{0.5}$Ga$_{0.5}$P$^{+}$-i-n$^{+}$ mesa photodiodes themselves (i.e., with the leakage current of the package subtracted) at the highest investigated reverse bias ($-30$ V), at 33°C, was $1.249 \pm 0.004$ pA (corresponding to a leakage current density of 3.97 $\pm 0.003$ nA/cm$^2$) for the 200$\mu$m and 400$\mu$m diameter device, respectively.

Detector capacitances were measured in dark conditions using an HP 4275A Multi-Frequency LCR meter with 50 mV rms magnitude and 1 MHz frequency test signal. The reverse bias, $V_{AR}$, from 0 V to $-30$ V, was applied during the capacitance measurements using a Keithley 6487 Picoammeter/Voltage Source. The uncertainty associated with the capacitance reading was $(0.1\% + 3 \text{ fF}) \times 1.2$. The uncertainty associated with the applied reverse bias was 0.1% of the applied bias plus 4 mV. The total uncertainty of the capacitance measurements of the packaged devices was estimated to be $\pm 0.02$ pF. The In$_{0.5}$Ga$_{0.5}$P$^{+}$-i-n$^{+}$ packaged diode capacitance as a function of applied reverse bias at 30°C can be seen in Fig. 2. The equivalent noise charge of the white series noise, ENCws, as calculated to arise from the capacitance of the In$_{0.5}$Ga$_{0.5}$P$^{+}$-i-n$^{+}$ photodiode detector at a shaping time of 6$\mu$s (see Sec. IV) can also be seen in Fig. 2.

The capacitance of the packaged 200$\mu$m diameter In$_{0.5}$Ga$_{0.5}$P$^{+}$-i-n$^{+}$ photodiode was found to decrease from 1.72 $\pm 0.02$ pF at no applied bias to 1.59 $\pm 0.02$ pF at $-30$ V applied reverse bias. Similarly, the capacitance of the 400$\mu$m diameter In$_{0.5}$Ga$_{0.5}$P$^{+}$-i-n$^{+}$ photodiode was found to decrease from 4.03 $\pm 0.02$ pF at no applied bias to 3.55 $\pm 0.02$ pF at $-30$ V applied reverse bias. No variation of capacitance with temperature was observed for either diode within the investigated temperature range, 33°C to 27°C. Assuming a packaging capacitance of 0.932 $\pm 0.001$ pF, which is consistent with previous measurements of the TO-5 cans’ packaging capacitance, the capacitance density of both photodiodes was found to be $2.08 \times 10^3$ pF cm$^{-2}$ at $-30$ V applied reverse bias, at 30°C. Subtracting the packaging capacitance from each packaged detector capacitance, the intrinsic capacitance was found to be 0.66 pF and 2.62 pF for the 200$\mu$m and the 400$\mu$m diameter In$_{0.5}$Ga$_{0.5}$P$^{+}$-i-n$^{+}$ photodiode, respectively, at $-30$ V applied reverse bias and a temperature of 30°C. The ratio of the photodiodes’ capacitances ($= 4$) was consistent with the ratio of the photodiodes’ areas. Assuming a parallel plate capacitance, the depletion layer width of each photodiode was calculated as a function of applied reverse bias (see Fig. 3). At low applied reverse biases, the depletion layer width of both devices increased as the applied reverse biased increased. Both the 200$\mu$m and the 400$\mu$m diameter In$_{0.5}$Ga$_{0.5}$P$^{+}$-i-n$^{+}$ mesa photodiodes were found to be fully depleted at $-1$ V. The depletion layer width at full depletion was calculated from these measurements to be 5.0 $\pm 0.4$ $\mu$m for the 200$\mu$m and 400$\mu$m diameter device, respectively.

**FIG. 1.** Leakage current and calculated ENCwp at 6$\mu$s shaping time as a function of applied reverse bias of the 200$\mu$m (circles) and the 400$\mu$m (squares) diameter In$_{0.5}$Ga$_{0.5}$P$^{+}$-i-n$^{+}$ mesa photodiode, with (filled symbols) and without (empty symbols) the leakage current of the package, at 30°C.

**FIG. 2.** Capacitance and calculated ENCws at 6$\mu$s shaping time as a function of applied reverse bias of the packaged 200$\mu$m (triangles) and the 400$\mu$m (diamonds) diameter In$_{0.5}$Ga$_{0.5}$P$^{+}$-i-n$^{+}$ mesa photodiodes, at 30°C.

**FIG. 3.** Calculated depletion layer width as a function of applied reverse bias of the 200$\mu$m (triangles) and the 400$\mu$m (diamonds) diameter In$_{0.5}$Ga$_{0.5}$P$^{+}$-i-n$^{+}$ mesa photodiodes, measured at 30°C.
and the 400 μm diameter device, respectively. The calculated depletion layer width was consistent with that indicated by measurements during the epitaxial growth. The uncertainty in the depletion layer width was determined predominantly by the Debye length (calculated for In0.5Ga0.5P with a doping concentration of 10^{14} cm^{-3} to be 0.4 μm at a temperature of 30 °C). In contrast, the measurement uncertainties in the capacitance measurements were calculated to be less than ±0.16 μm and less than ±0.04 μm for the 200 μm and the 400 μm diameter devices, respectively.

IV. ENERGY LINEARITY MEASUREMENTS

The two In0.5Ga0.5P p⁺-i-n⁺ mesa photodiode detectors (one with 200 μm diameter, one with 400 μm diameter) were each connected, in turn, to the input of the same custom-made single channel charge-sensitive preamplifier. The preamplifier was of feedback resistorless design, similar to Ref. 41. It had a Vishay Siliconix 2N4416A JFET as the input transistor. A custom-made Al collimator, lined with polytetrafluoroethylene (PTFE) (to absorb all fluorescence from the Al of the collimator), was used to collimate the X-rays from the Mo target X-ray tube. A custom-made Al enclosure with a 4 μm thick Al window. The Al enclosure was installed within a LD Didactic GmbH X-ray apparatus (part number 554 801) with a Mo target X-ray tube. The Al enclosure was attached to the goniometer of the apparatus for precise positioning. The detector-preamplifier system was positioned on the sample stand of the X-ray apparatus at 45° to the collimator. The detector-preamplifier system was positioned at 135° to the collimator. This arrangement ensured the maximum detection of X-ray fluorescence from the samples and minimum detection of X-rays directly from the tube. The X-ray tube voltage and current were set to 35 kV and 1 mA, respectively. X-ray spectra of each foil were accumulated with both spectrometers. The live times were 4 h and 1 h for the spectrometer with the 200 μm and the 400 μm diameter detector, respectively, thus in proportion to the detectors’ areas. In each case, the detector was reverse biased at −5 V and the shaping time of the shaping amplifier was set to 6 μs.

Gaussians were fitted to the peaks of the spectra accumulated with the foils. The position of the centroid of each fitted fluorescence peak on the MCA scale along with that peak’s accepted energy was used to deduce the energy calibrations of both systems. Figure 4 shows the positions of the peaks’ centroids on the MCA scale as a function of photon energy. The lines of best fit were calculated using linear least squares fitting. The error bars, associated with the fitting for each data point, computed to be ±3 channels and ±2 channels for the spectrometer employing the 200 μm and 400 μm diameter detector, respectively, were obtained from

\[ S = \sqrt{\frac{\sum (C_N' - C_N)^2}{n - 2}}, \]

where \( C_N' \) is the experimentally determined channel number (position of the centroid) of each photopeak, \( C_N \) is the channel number as calculated using the linear least squares fitting (see Fig. 4), and \( n \) is the number of data points (number of X-ray lines used) for the linear least squares fitting (see Table II). The numerator within the square root was the sum of squared residuals, and the denominator was the number of degrees of freedom associated with the sum of squared residuals. Since the error bars were comparable to

![Graph](image)

The X-ray fluorescence calibration samples were positioned on the sample stand of the X-ray apparatus at 45° to the collimator. The detector-preamplifier system was positioned at 135° to the collimator. This arrangement ensured the maximum detection of X-ray fluorescence from the samples and minimum detection of X-rays directly from the tube. The X-ray tube voltage and current were set to 35 kV and 1 mA, respectively. X-ray spectra of each foil were accumulated with both spectrometers. The live times were 4 h and 1 h for the spectrometer with the 200 μm and the 400 μm diameter detector, respectively, thus in proportion to the detectors’ areas. In each case, the detector was reverse biased at −5 V and the shaping time of the shaping amplifier was set to 6 μs.

Gaussians were fitted to the peaks of the spectra accumulated with the foils. The position of the centroid of each fitted fluorescence peak on the MCA scale along with that peak’s accepted energy was used to deduce the energy calibrations of both systems. Figure 4 shows the positions of the peaks’ centroids on the MCA scale as a function of photon energy. The lines of best fit were calculated using linear least squares fitting. The error bars, associated with the fitting for each data point, computed to be ±3 channels and ±2 channels for the spectrometer employing the 200 μm and 400 μm diameter detector, respectively, were obtained from

\[ S = \sqrt{\frac{\sum (C_N' - C_N)^2}{n - 2}}, \]

where \( C_N' \) is the experimentally determined channel number (position of the centroid) of each photopeak, \( C_N \) is the channel number as calculated using the linear least squares fitting (see Fig. 4), and \( n \) is the number of data points (number of X-ray lines used) for the linear least squares fitting (see Table II). The numerator within the square root was the sum of squared residuals, and the denominator was the number of degrees of freedom associated with the sum of squared residuals. Since the error bars were comparable to

![Graph](image)

The X-ray fluorescence calibration samples were positioned on the sample stand of the X-ray apparatus at 45° to the collimator. The detector-preamplifier system was positioned at 135° to the collimator. This arrangement ensured the maximum detection of X-ray fluorescence from the samples and minimum detection of X-rays directly from the tube. The X-ray tube voltage and current were set to 35 kV and 1 mA, respectively. X-ray spectra of each foil were accumulated with both spectrometers. The live times were 4 h and 1 h for the spectrometer with the 200 μm and the 400 μm diameter detector, respectively, thus in proportion to the detectors’ areas. In each case, the detector was reverse biased at −5 V and the shaping time of the shaping amplifier was set to 6 μs.

Gaussians were fitted to the peaks of the spectra accumulated with the foils. The position of the centroid of each fitted fluorescence peak on the MCA scale along with that peak’s accepted energy was used to deduce the energy calibrations of both systems. Figure 4 shows the positions of the peaks’ centroids on the MCA scale as a function of photon energy. The lines of best fit were calculated using linear least squares fitting. The error bars, associated with the fitting for each data point, computed to be ±3 channels and ±2 channels for the spectrometer employing the 200 μm and 400 μm diameter detector, respectively, were obtained from

\[ S = \sqrt{\frac{\sum (C_N' - C_N)^2}{n - 2}}, \]

where \( C_N' \) is the experimentally determined channel number (position of the centroid) of each photopeak, \( C_N \) is the channel number as calculated using the linear least squares fitting (see Fig. 4), and \( n \) is the number of data points (number of X-ray lines used) for the linear least squares fitting (see Table II). The numerator within the square root was the sum of squared residuals, and the denominator was the number of degrees of freedom associated with the sum of squared residuals. Since the error bars were comparable to
the inherent analytical uncertainties from experimentally determining the position of the centroid of each peak in the spectra (typically ±3 channels), it can be said that the voltage outputs of both systems had linear relationships with photon energy. The width of each channel was computed to be 7 eV and 9 eV for the spectrometer employing the 200 μm and 400 μm diameter detector, respectively. The residuals of the fit in percentage terms were also evaluated; they were found to be less than ±0.3% and less than ±0.4% for the 200 μm and the 400 μm diameter device systems, respectively.

An example X-ray fluorescence spectrum of the Mn foil obtained using the spectrometer with the 200 μm diameter detector can be seen in Fig. 5. The detected peak is the combination of the Mn Kα and Mn Kβ lines at 5.9 keV and 6.49 keV, respectively.44 the energy resolution was not sufficient to resolve the individual lines. The dashed lines shown in Fig. 5 represent the Gaussians fitted to the peak taking into account the relative emission ratio44 and the relative efficiency of the detector at 5.9 keV (Mn Kα) and 6.49 keV (Mn Kβ). The energy calibration of the MCA’s charge scale of the spectrum was achieved using the relationship presented in Fig. 4. The counts of the zero energy noise peak of the spectrum were limited by setting the MCA low energy cutoff at 1.7 keV; a small portion of the right hand side of the tail can still be seen in Fig. 5. Spectra of this nature were obtained for all of the calibration foils.

The energy resolution of each photopeak in the spectra, accumulated using both spectrometers, was measured and can be seen in Fig. 6. It was found to increase from 0.79 ± 0.02 keV at 4.95 keV to 0.83 ± 0.02 keV at 21.17 keV, and from 1.12 ± 0.02 keV at 4.95 keV to 1.15 ± 0.02 keV at 21.17 keV, for the spectrometer employing the 200 μm and the 400 μm diameter detector, respectively. The energy resolution of an X-ray spectrometer consisting of a non-avalanche photodiode detector coupled to a charge sensitive preamplifier is degraded due to Fano noise, electronic noise, and incomplete charge collection noise.45 The Fano noise, ΔE_F, is energy dependent; it increases with increasing photon energy, E, as per

$$\Delta E_F (eV) = (8 \ln 2)^{0.5} \omega \sqrt{FE} \omega$$, \hspace{1cm} (2)

where ω is the electron-hole pair creation energy and F is the Fano factor.46 The incomplete charge collection noise is also photon energy dependent, whereas the electronic noise is photon energy invariant. The incomplete charge collection noise was found to be negligible at −5 V reverse bias;26 thus, the quadratic sum of the Fano noise and the electronic noise, ΔE_E,

$$\Delta E (eV) = \sqrt{8 \ln 2oFE} + \Delta E^2_E$$, \hspace{1cm} (3)

defined the FWHM. The Fano factor and the electronic noise were determined by fitting Eq. (3) to the measured FWHM as a function of energy (Fig. 6), assuming an electron hole pair creation energy of 4.95 ± 0.07 eV at 300 K.27 The minimization of the sum of the squares of the residuals between the fitting and the measured FWHM for both spectrometers suggested a Fano factor of 0.13. This value is comparable to Fano factor values previously reported for other semiconductors such as 4H-SiC (=0.10),6 Si (=0.12),47 Ge (=0.11),47 GaAs (=0.12-0.14),48,49 and CdTe (=0.15).50 The Fano noise was calculated to increase from 133 eV at 4.95 keV to 275 eV at 21.17 keV, and to be 145 eV at 5.9 keV. The electronic noise was calculated to be 0.77 ± 0.02 keV and 1.13 ± 0.02 keV within the investigated energy range, for the spectrometer employing the In0.5Ga0.5P 200 μm and the 400 μm diameter detector, respectively. Its rms deviance, attributed to the error in fitting the photopeaks, was estimated to be ±0.02 keV. The quadratic sum of the derived electronic noise and the calculated Fano noise, comprising the predicted FWHM, can be seen in Fig. 6. Since these values were in good agreement with the measured FWHM, the increase of the FWHM with increased energy was solely attributed to the increase of the Fano noise, and thus, the absence of significant incomplete charge collection noise was confirmed.
The white parallel noise (arising from the leakage current), ENCWP, and white series noise (arising from the capacitance), ENCWS, contributions of the In0.5Ga0.5P detectors were calculated according to Lioliou and Barnett, at 6 μs shaping time and can be seen in Figs. 1 and 2, respectively. The ENCWP was calculated to be ≤8 e−rms for both In0.5Ga0.5P detectors. However, the ENCWS was calculated to vary among the two different diameter devices, due to their different capacitances; 5 e−rms and 12 e−rms at 6 μs and at −5 V reverse bias were calculated for the 200μm and the 400 μm diameter device, respectively. The difference in electronic noise between the two spectrometers was attributed to the higher capacitance of the 400 μm diameter device compared to the capacitance of the 200 μm diameter device, resulting in higher white series noise (ENCWS) and dielectric noise (proportional to the capacitance of the lossy dielectrics, including the semiconductor photodiodes themselves in the spectrometer employing the 400 μm diameter devices compared to that with the 200 μm diameter device.

V. LINEARITY WITH X-RAY INTENSITY

For the energy calibration of the system, the X-ray flux incident on the detector was maximised by setting the Mo target X-ray tube current, Xc, to 1.0 mA. Here, the current of the X-ray tube was varied to investigate the non-linearity of the system (count rate) as a function of X-ray flux.

Additional spectra of two of the fluorescence calibration foils, Zn (Kα = 8.63 keV) and Nb (Kα = 16.61 keV), were accumulated following the same procedure as for the energy calibration of the system, with both In0.5Ga0.5P p+-i-n+ mesa photodiodes, to investigate the linearity of the spectrometers as a function of X-ray fluorescence. The difference between the spectra obtained here and the spectra obtained for the energy calibration (Sec. IV) was that the Mo target X-ray tube current, Xc, was varied from 0.2 mA to 1.0 mA, in 0.2 mA steps. The detected count rate, R (in units of counts s−1), defined as the number of counts within the Gaussians fitted to each of the Kα peaks of Zn (8.63 keV) and Nb (16.61 keV) over the spectrum accumulation time, was determined as a function of X-ray tube current using both photodiodes and can be seen in Fig. 7.

The incident photon fluences can be estimated from the detected count rates and the quantum efficiencies of the detectors. The quantum detection efficiency,

\[QE = \prod_m \exp(-\mu_m v_m) \left[1 - \exp(-\mu_{InGaP} x_{InGaP})\right]\]  

(4)

of the 200 μm (400 μm) diameter detector was calculated to be 0.2298 (0.2317) at 8.63 keV and 0.0776 (0.0780) at 16.61 keV. In Eq. (4), μm and xm are the linear attenuation coefficient and the thickness of the mth dead layer (Au/Ti contact, and GaAs buffer layer), respectively, and μInGaP and xInGaP are the linear attenuation coefficient and the thickness of the active layer (p+ layer and i layer). The different percentages of the 200 μm and the 400 μm diameter detectors’ top faces being covered by the top contacts were considered in the quantum detection efficiency calculations; 33% and 45% were covered by the top contacts in the 400 μm diameter and the 200 μm diameter detector, respectively.

Linear relationships were found between the count rates within the Kα fluorescence peaks of Zn and Nb and the X-ray tube current. Figure 7 shows the lines of best fit, calculated using linear least squares fitting. The responses of the spectrometers were found to be linear across the ranges measured. The minimum and maximum investigated incident fluences at 8.63 keV and 16.61 keV, as estimated from the detected count rates and the quantum efficiencies of the detectors for both spectrometers, can be seen in Table III.

Taking into account the different sizes and QE of the detectors, the count rate of the 400 μm diameter detector was expected to be greater than that of the 200 μm detector by a factor of 4.03 at 8.63 keV and 4.02 at 16.61 keV. The experimentally measured count rates however, obtained from the data presented in Fig. 7, corresponded to 4.23 at 8.63 keV and 4.58 at 16.61 keV. The differences between the expected and measured values were attributed to slight differences in the placement of each detector within the preamplifier housing rather than differences in their fundamental characteristics.

| TABLE III. Minimum and maximum detected count rates (given in units of counts s−1) and estimated incident photon fluences (given in units of photons s−1 cm−2) at 8.63 keV and 16.61 keV for both spectrometers. |
|-----------------|-----------------|-----------------|-----------------|-----------------|
| 200 μm diameter detector | 400 μm diameter detector |
| Detected counts s−1 | Incident photons s−1 cm−2 | Detected counts s−1 | Incident photons s−1 cm−2 |
| 8.63 keV | 1.3 × 10⁵ | 42 | 1.4 × 10⁵ |
| Max | 6.7 × 10⁵ | 205 | 7.0 × 10⁵ |
| 16.61 keV | 1.5 × 10⁵ | 17 | 1.7 × 10⁵ |
| Max | 7.4 × 10⁵ | 83 | 8.5 × 10⁵ |
VI. CONCLUSIONS

Two In$_{0.5}$Ga$_{0.5}$P p$^+$-i-n$^+$ mesa photodiodes (a 200$\mu$m and a 400$\mu$m diameter device) each with a 5$\mu$m thick layer have been investigated for their suitability as detectors for photon counting X-ray spectroscopy within the energy range 4.49 keV and 21.17 keV. The detectors and associated preamplifier electronics were operated uncooled at 30 ± 3 °C. The detectors were initially electrically characterized in the temperature range of interest. The diodes were then coupled, each in turn, to the same charge sensitive preamplifier, shaping amplifier, and MCA. X-ray fluorescence spectra of high-purity calibration samples were accumulated. The samples were fluoresced by a Mo target X-ray tube.

The leakage currents of the packaged In$_{0.5}$Ga$_{0.5}$P p$^+$-i-n$^+$ mesa photodiodes were ≤0.2 pA (≤8 e$^-$ rms ENC$_{WP}$ at 6 $\mu$s) at the operating reverse bias of −5 V. Packaged devices' capacitances of 1.59 ± 0.02 pF (5 e$^-$ rms ENC$_{WS}$ at 6 $\mu$s) and 3.58 ± 0.02 pF (12 e$^-$ rms ENC$_{WS}$ at 6 $\mu$s) were measured for the 200$\mu$m diameter and the 400$\mu$m diameter device, respectively, at −5 V applied bias. Both photodiodes were found to be fully depleted at this applied reverse bias.

For each detector coupled to the spectrometer electronics in turn, linear relationships between the spectrometer charge and a 400$\mu$m diameter device, respectively, at −5 V applied bias. Both photodiodes were found to be fully depleted at this applied reverse bias.

All the above results suggested that the In$_{0.5}$Ga$_{0.5}$P devices reported here were able to be used for photon counting X-ray spectroscopy at a temperature of 30 ± 3 °C, operating uncooled with good energy resolutions and linear responses. This is in contrast to its parent binary compounds, GaP and InP, which have been reported to not be spectroscopic at room temperature. Although the FWHM at 5.9 keV achieved with the In$_{0.5}$Ga$_{0.5}$P devices were not as good as the best achieved with 4H-SiC (196 eV at 5.9 keV, at 30 °C) and GaAs (266 eV at 5.9 keV, at 23 °C), the In$_{0.5}$Ga$_{0.5}$P devices were limited by the noise of the preamplifier electronics rather than the characteristics of the detectors themselves. Improvements in energy resolution would be expected if the In$_{0.5}$Ga$_{0.5}$P detectors presented here were coupled to a lower noise preamplifier. However, the energy resolutions (FWHM at 5.9 keV) reported here are already better than those reported using Cd$_{1-x}$Zn$_x$Te (e.g., 1.6 keV at 23 °C). In$_{0.5}$Ga$_{0.5}$P based spectrometers may find uses in future planetary science and astrophysics space missions, as an alternative to Cd$_{1-x}$Zn$_x$Te, for the detection of hard X-rays and γ-rays, or for the detection of X-rays and γ-rays in environments of high temperature.
